Probiotics in prevention of antibiotic associated diarrhoea: meta-analysis

Aloysius L D'Souza, Chakravarthi Rajkumar, Jonathan Cooke, Christopher J Bulpitt

Abstract

Objective To evaluate efficacy of probiotics in prevention and treatment of diarrhoea associated with the use of antibiotics.

Design Meta-analysis; outcome data (proportion of patients not getting diarrhoea) were analysed, pooled, and compared to determine odds ratios in treated and control groups.

Identification Studies identified by searching Medline between 1966 and 2000 and the Cochrane Library. Studies reviewed Nine randomised, double blind, placebo controlled trials of probiotics.

Results Two of the nine studies investigated the effects of probiotics in children. Four trials used a yeast (Saccharomyces boulardii), four used lactobacilli, and one used a strain of enterococcus that produced lactic acid. Three trials used a combination of probiotic strains of bacteria. In all nine trials, the probiotics were given in combination with antibiotics and the control groups received placebo and antibiotics. The odds ratio in favour of active treatment over placebo in preventing diarrhoea associated with antibiotics was 0.39 (95% confidence interval 0.25 to 0.62; P < 0.001) for the yeast and 0.34 (0.19 to 0.61; P < 0.01 for lactobacilli. The combined odds ratio was 0.37 (0.26 to 0.53; P < 0.001) in favour of active treatment over placebo.

Conclusions The meta-analysis suggests that probiotics can be used to prevent antibiotic associated diarrhoea and that S boulardii and lactobacilli have the potential to be used in this situation. The efficacy of probiotics in treating antibiotic associated diarrhoea remains to be proved. A further large trial in which probiotics are used as preventive agents should look at the costs of and need for routine use of these agents.

Introduction

Biological agents (“biotherapeutic agents” or “probiotics”) have been used to treat a variety of infections, most notably infections of mucosal surfaces such as the gut and vagina (box). After the discovery and development of antibiotics, the value of these traditional treatments diminished. Now, however, we are being forced to look at alternatives to antibiotics to combat the ever increasing number of infections that occur because of excessive use of antibiotics.

The term “probiotic” was first used to describe “a live microbial supplement, which beneficially affects the microbial balance of the host.

- Probiotics have special properties that make them useful in fighting infections of mucosal surfaces such as the gut and vagina
- Different species of lactobacilli have the potential for use in clinical practice as also the yeast Saccharomyces boulardii
- Probiotics are becoming increasingly available as capsules and dairy based food supplements sold in health food stores and some supermarkets
- The relative lack of side effects makes probiotics a possible way of preventing antibiotic associated diarrhoea

Materials and methods

Literature search
We searched Medline between 1966 to 2000 with the terms “probiotics,” “biotherapeutic agents,” “lactobacilli,” “antibiotic associated diarrhoea,” and “Clostridium difficile.” We also searched the Cochrane Controlled Trials Register and the Cochrane Database of System-

The key outcome data taken for analysis included the sample size (table 1), treatment regimens, and numbers of patients in both arms of the study who had an absence of diarrhoea (table 2).

Quantitative data synthesis and validity assessment
We used the percentage of patients without diarrhoea in the probiotic and placebo groups as an outcome measure. We defined diarrhoea as "a change from the patient’s normal bowel habit, with two or more loose or watery stools for at least two days." We performed three separate analyses: one for the four prevention trials using *S boulardii*, one for the five trials using lactobacilli or enterococci, and one on pooled data from all nine trials.

We ensured that the odds ratios were not heterogeneous across the trials by performing tests of homogeneity across all nine trials (*P = 0.246*), across the four yeast trials (*P = 0.065*), and across the five non-yeast trials (*P = 0.573*). As these tests did not achieve significance, we combined the information in the tables using the Mantel-Haenszel method. We also calculated summary odds ratios and 95% confidence intervals for these analyses, and we plotted a graph by using the log of the odds ratios to determine the benefit of treatment over placebo.

Publication bias
A funnel plot (fig 1) did not show any publication bias; it showed that the larger studies found benefit and the smaller studies gave results varying from good to no benefit. Two further tests were carried out to investigate possible publication bias—the Begg and Mazumdar adjusted rank correlation test for publication bias and the Egger et al regression asymmetry test for publication bias.

The Begg and Mazumdar adjusted rank correlation test is a direct statistical analogue of the visual funnel graph (fig 1). Note that both the test and the funnel graph have low power for detecting publication bias. The Begg and Mazumdar procedure tests for publication bias by determining if there is a significant correlation between the effect estimates and their variances. When this test was used on the data, a P value of 0.297 was obtained.

The Egger et al regression asymmetry test and the regression asymmetry plot tend to suggest publication bias more often than the Begg approach. The Egger test detects funnel plot asymmetry by determining whether the intercept deviates significantly from zero in a regression of the standardised effect estimates against their precision. Egger’s test for bias gave a P value of 0.08 and the confidence interval included zero.

The Begg and Egger tests provide graphical output (figs 2 and 3). In figure 3, the regression asymmetry graph plots the standardised effect estimates (odds ratio) against precision (1 divided by standard error) along with the variance weighted regression line and the confidence interval about the intercept. Failure of this confidence interval to include zero indicates asymmetry in the funnel plot and may give evidence of publication bias. Guide lines at x = 0 and y = 0 are plotted to help determine visually whether zero is in the confidence interval. As this test did include zero, we concluded that publication bias was not present in our meta-analysis.

Results
Nine trials were included in the final analysis (fig 4). The study regimens used probiotics combined with one antibiotic or a variety of antibiotics (table 2). All trials studied the efficacy of a probiotic in the prevention of antibiotic associated diarrhoea. The numbers of patients and the duration of follow up varied greatly from study to study, but the patients’ characteristics were similar for the active treatment and placebo groups within each study.

We calculated the odds ratio on the basis of the proportion of patients free of diarrhoea on treatment compared with that in control groups. After tests of homogeneity, summary odds ratios and 95% confidence interval limits were provided for the combined data of the four trials that used *S. boulardii* (yeast trials), the five non-yeast trials, and all nine trials together. The combined odds ratios for the four yeast trials and for the five non-yeast trials were similar (0.39 (95% confidence interval 0.25 to 0.62) and 0.34 (0.19 to 0.61), respectively); both favoured active treatment over placebo in the prevention of antibiotic associated diarrhoea. The odds ratio for pooled data from all nine trials was in favour of active treatment over placebo in the prevention of antibiotic associated diarrhoea (0.37; 0.26 to 0.53). Six studies showed a significant benefit of probiotic treatment compared with placebo (P < 0.05) (fig 5). One study showed benefit for only a subgroup of patients who did not receive non-antibiotic drugs likely to induce diarrhoea, such as magnesium hydroxide (for constipation), lactulose, and bisacodyl (for hepatic encephalopathy).

Findings
McFarland et al showed that *S. boulardii* lessened diarrhoea associated with antibiotics that contain a β-lactam ring and prevented recurrent *C. difficile* infection when given in combination with standard antibiotics. There was no benefit, however, when *S. boulardii* was used to treat primary infection with *C. difficile*. Schellenberg et al reported success with brewer’s yeast, *S. cerevisiae*, for the treatment of *C. difficile* colitis. This finding was criticised in one paper, but was supported in another.

*Lactobacillus* GG was successfully used to treat a group of patients with recurrent diarrhoea caused by *C. difficile*. Vanderhoof et al showed a significant reduction in antibiotic associated diarrhoea, using this agent in children. The other trials in our meta-
analysis used different strains of lactobacilli, two trials used two different strains of lactobacilli in combination. In Wunderlich et al showed that the strain of enterococcus strain SF68 that produced lactic acid was useful. In the Orrhage study, a combination of L acidophilus and Bifidobacterium survived in the human gut and reduced the faecal counts of clostridia.

**Discussion**

Our meta-analysis of trials that used live organisms to prevent diarrhoea associated with antibiotics shows that probiotics may be effective in preventing antibiotic associated diarrhoea. We had only a small number of trials in our meta-analysis, and it should be noted that the different antibiotics used in the trials may have altered the risk of patients getting diarrhoea and their response to the probiotics. Although probiotics have been used to prevent or treat diarrhoea of other causes—namely traveller’s diarrhoea and infantile infectious diarrhoea—we did not include trials that investigated probiotics in these indications; however, most of these studies showed positive results, and some reviews have been encouraging.

The way in which probiotics affect the gut has drawn much interest. To combat the problems of gastrointestinal infection, a probiotic must be non-pathogenic and must act against pathogens by different mechanisms from antibiotics—for example, by competition. More importantly, they should have a fairly rapid onset of action and survive the challenges of gastric acid, bile, or concurrent antibiotics. It is also desirable that they modify immune processes to destroy the invading organism. *Saccharomyces boulardii* and lactobacilli display these common properties.

A few live organisms have been used in many trials. *S boulardii*, a non-pathogenic yeast, is one such organism. It has a growth temperature of 37°C, rapidly colonises the bowel, does not alter the normal gut flora, and is cleared from the colon after treatment is discontinued. Of the four yeast trials, two studies individually showed significant benefits, but one did not; differences in the dose and duration of treatment with *S boulardii* and variations in the period of follow up may explain this disparity. Interestingly, *S boulardii* can also destroy the receptor site for *C difficile* toxin A and B by producing a protease; this could explain how *S boulardii* was noted to reduce the frequency of toxin B positivity. This finding was criticised, but it was also supported.

The other probiotic agent used widely in clinical trials is the *Lactobacillus* species. The mechanism of action of lactobacilli may be through multiple means: *Lactobacillus* GG has shown beneficial effects on intestinal immunity, it increases the numbers of cells that secrete immunoglobulin G and other immunoglobulins in the intestinal mucosa, and it stimulates the local release of interferon. It also facilitates antigen transport to underlying lymphoid cells, and shows increased uptake in Peyer’s patches. *Lactobacillus* GG has also been shown to produce an antimicrobial substance that inhibits the growth of *Escherichia coli*, streptococci, *C difficile*, *Bacteroides fragilis*, and *Salmonella*. *L casei shirota* also showed good survival in the gut in separate studies, and mucosal antibody titres (specific to lactobacilli) were increased in the presence of this agent. Although there was no discernable change to the numbers of clostridia or enterococci, there was an increase in the numbers of excreted bifidobacteria—a normal bowel anaerobe. It is possible that this increase in bifidobacteria interferes with the pathogenic potential of *C difficile*.

Advantages of *S boulardii* over current clinical practice include its ready availability in the form of breuer’s yeast, its easy administration, and the remarkable cost effectiveness of its use compared with vancomycin when infection occurs. However, there is a risk of fungaemia in immunocompromised patients and of endocarditis in those with damaged or artificial heart valves who have been treated with lactobacilli; it would seem prudent to avoid using lactobacilli in such patients.
What is already known on this topic

Probiotics are well known for their microbiological properties and have been used to treat gastrointestinal and vaginal mucosal infections. Conflicting results have prevented probiotics from being accepted as viable alternatives to conventional treatments for antibiotic associated diarrhea.

The commercial availability of probiotics is increasing.

What this study adds

Probiotics may prevent antibiotic associated diarrhea.

The potential of specific probiotics to prevent Clostridium difficile infection secondary to the use of antibiotics should be re-examined.

A large trial looking at the efficacy of probiotics in preventing antibiotic associated diarrhea, particularly in elderly patients, with an emphasis on the optimal dose and cost benefits is needed.

Probiotics are a possible solution in the prevention of antibiotic associated diarrhea. Clostridium difficile infection is increasingly prevalent in today's hospital setting, particularly in elderly patients, in whom 10-20% of such cases occur.26 The incidence of antibiotic associated diarrhea depends on the antibiotic used and each individual patient's risk factors. The standard regimens to treat colitis constiuents associated with Clostridium difficile are metronidazole and vancomycin; although these drugs are successful in 80% of cases, about 20% of patients suffer from recurrence.27 In light of the need to control costs in these days of managed health care, we must re-examine the benefits of using live organisms. Whether the use of probiotics can actually reduce the length of hospital stay by reducing the incidence of infection with C difficile and the need to use antibiotics such as metronidazole and vancomycin are issues that need to be addressed in a clinical trial.

Conclusion

Our meta-analysis of nine trials shows that biotherapeutic agents may be useful in preventing antibiotic associated diarrhea, but it provides little support for a role of probiotics in the treatment of such diarrhea. The increasing availability, lower costs, and relative lack of side effects of probiotics contrast with the problems associated with current antibiotic regimens. Commercially available strains are being marketed in capsules and yoghurt based drinks, but their potential benefit needs further investigation. It would be wrong to credit the proved benefits of one strain to an untested but closely related strain.28 Data from trials have provided us with clear evidence on the efficacy of some strains in the gut, but we still need to see confirmation of their clinical benefit.

Contributors: CJB had the original plan for the meta-analysis, researched individual papers, offered statistical advice, and edited the final paper. AD'S conducted the online and other searches, researched individual papers, extracted output data from individual trials, and wrote the paper. JC was responsible for the statistical analysis, calculated final output data and odds ratios, drew the final graph, and conducted tests of publication bias. CR researched individual papers and assisted in the preparation of the article.

Science commentary: Probiotics

Abi Berger science editor, BMJ

Probiotics are microbes that protect their host, and in some cases they can prevent disease. They are immunomodulating bacteria that have very low virulence compared with the more pathogenic gut flora such as Escherichia coli and clostridia. Lactobacilli and bifidobacteria are examples of probiotics found in the large intestine.

Lactobacillus GG can prevent diarrhoea and atopy in children.1 In the gut, probiotic bacteria are thought to occupy binding sites on the gut mucosa, preventing pathogenic bacteria from adhering to the mucosa. Lactobacilli also produce protease and lipase enzymes—bacterial toxins—that act as local antibiotics against more pathogenic organisms. But what is known about what happens in vitro cannot necessarily be extrapolated to the complexity of the ecosystem of the human gut.

Diarrhoea associated with antibiotics is presumed to result from the antibiotics disrupting the normal flora in the gut of a healthy person. Such disruptions can cause dysfunction of the gut's ecosystem, and they may allow pathogenic bacteria to colonise the gut and gain access to the mucosa. Whether probiotic supplements stop this process by reducing the diarrhoea or by acting as substitutes for the healthy flora is unclear. Probiotics may compete with pathogens for the nutrients the pathogens need to grow, or they may modify toxins produced by pathogens or toxin receptors found in the gut wall, or they may stimulate immune responses to pathogens.

The exact mechanisms by which probiotics prevent atopy are still under debate. One suggestion is that the establishment and maintenance of innate immune tolerance is mediated by T helper 1 cells and linked in some way to the faecal flora. If the Th1 response is particularly robust, the allergic response mediated by T helper 2 cells tends not to be so strong. Probiotics may prevent atopy by supporting the faecal flora, strengthening the Th1 response, and reducing the allergic response.

In the countries of continental Europe, probiotics are regarded as medicines, and they are prescribed alongside antibiotics. In other countries, probiotics are marketed as supplements and are sold over the counter—although preparations such as “bioyoghurts” do not always contain probiotic strains proved to be clinically useful.
